Three experiments were conducted to determine the relative accessibility of semantic and deep-structure syntactic concepts. In Experiment 1, which employed a concept-generation task, subjects learned the concept "deep-structure subject" more slowly than the case concept "experiencer." In Experiments 2 and 3, which employed a new recognition memory procedure, subjects performed more poorly when the sentences to be remembered were differentiated on the basis of deep-structure syntactic relations than when they were differentiated on the basis of semantic relations. These results favor Fillmore's case grammar, or another semantically based theory, rather than the "standard theory" of Chomsky in a model of linguistic behavior.

A number of different versions of transformational generative grammar have been proposed in recent years, including, among others, "generative semantics" (Lakoff, 1971; McCawley, 1968), case grammar (Fillmore, 1968, 1970, 1971, 1977), and the "standard theory" of Chomsky (1965). One aspect of the standard theory that is attacked by the proponents of both case grammar and generative semantics is syntactic deep structure as a level of linguistic description. Syntactic deep structure plays a prominent role in the standard theory. In fact, the deep syntactic level of representation is central. The deep syntactic representation is mapped into a semantic representation, on one hand, and into a surface syntactic representation, on the other hand. A system of semantic projection rules (Katz & Fodor, 1963) is posited to link the deep syntactic and semantic levels, and such a system of syntactic transformations is posited to link the deep syntactic and surface syntactic levels. In contrast, according to generative semantics, the level of syntactic deep structure is not necessary. Rather, the semantic representation is mapped directly into a surface syntactic representation. A single system of transformational rules is envisioned to link the semantic and surface syntactic representations. Likewise, a purely syntactic level of deep structure is not included in case grammar and, in fact, was deemed "an artificial intermediate level" by Fillmore (1968, p. 88). According to case grammar, case relations, which are semantic as well as syntactic, replace the purely syntactic deep-structure relations, such as deep-structure (logical) subject. Although the standard theory and case grammar posit essentially identical surface-structure representations (see Figure 1), the deep-structure representations differ substantially (see Figure 2). Note in particular that, whereas the relation deep-structure subject can be defined in terms of the deep structure of the standard theory (technically, the subject is the noun phrase immediately dominated by the node labeled S), the relation deep-structure subject cannot be simply defined in terms of the deep structure of case grammar. Rather, in case grammar the subject of the sentence is treated in an entirely parallel manner to the other cases in the deep structure, and the relation subject is "seen as exclusively a surface-structure phenomenon" (Fillmore, 1968, p. 17). Only as a result of subject selection and transformational rules is a subject created and placed into its proper location in the surface structure of the sentence.

This research was supported in part by PHS Grants MH26573 and RR07015, NSF Grant BNS-77-00077 to Yale University, and NICHD Grant HD01994 and BRSG Grant RR05596 to Haskins Laboratories. The senior author was supported by a Junior Faculty Fellowship from Yale University during the preparation of this manuscript. The authors are deeply indebted to Guy Carden for many informative discussions, Robert G. Crowder for a careful reading of an earlier version of this manuscript, George A. Miller for inspiring us to perform Experiment 3 and for other valuable suggestions, Jonathan Livingston for help with the design of Experiment 1 and help with the construction of the sentences used in Experiments 1 and 2, Wendy Brown for help with the conduct and analyses of Experiments 1 and 2, Oren Patashnik for help with the conduct and analyses of Experiment 1, and Loretta Polka for help with the conduct and analyses of Experiment 3. Portions of this paper concerning Experiments 1 and 2 were read at the Eighteenth Annual Meeting of the Psychonomic Society, Washington, D.C., November 1977. ACCESSIBILITY OF DEEP-STRUCTURE SYNTACTIC CONCEPTS

Surface Structure Representation:
"The doctor gave the books to John."

Case Grammar

Deep Structure Representation:
"The doctor gave the books to John."

Instead of employing the cued-recall technique used in the studies reviewed above, in the present study, we used a concept-formation task, which enabled us to assess the extent to which subjects are able to learn by example various syntactic and semantic concepts. This technique was employed by Baker, Prideaux, and Derwing (1973) to study surface-structure syntactic concepts and by Shafto (1973) to study the semantic concepts of case grammar. Although Shafto successfully studied the ease of learning various case relations (and found “agent” easiest, followed by “experiencer,” followed by “instrument” and “object”), he did not compare case concepts to any other linguistic concepts. In Experiment 1 of the present study, we compared the ease of learning a case relation and a deep-structure syntactic relation. Two baseline conditions were also included in this experiment, one to provide information about the upper limit of performance and the other to provide information about the lower limit of performance. In the first baseline condition, subjects learned a surface-structure syntactic relation, expected to be relatively trivial, and in the second baseline condition, subjects learned an arbitrary relation, defined in a manner analogous to that of the other three concepts.

It should be noted that, although case relations were specifically manipulated in this investigation, this study does not allow us to discriminate among various
semantically based grammars, since differences in case relations are necessarily confounded with differences in other semantic variables. Likewise, this investigation does not allow us to discriminate among different models of sentence memory and comprehension that assert structures of a semantic variety (e.g., Anderson & Bower, 1973; Kintsch, 1974; Rumelhart, Lindsay, & Norman, 1972; Schank, 1972). However, this study enables us to discriminate between such models based primarily on semantic relations and any plausible alternative models based primarily on deep-structure syntactic relations.

EXPERIMENT 1

This experiment employed lists of simple sentences, each of which included the word “John” in one of two semantic roles (“experiencer” or “goal”), one of two deep-structure syntactic categories (deep-structure subject or deep-structure object of the preposition), and one of two surface-structure syntactic categories (surface-structure subject or surface-structure object of the preposition). Although there are eight possible combinations of these three kinds of relations, only six of them (Types 1-6) were employed here (see Table 1). Two combinations (Types 7 and 8)—deep-structure object of the preposition, surface-structure subject, experiencer, and deep-structure subject, surface-structure object of the preposition, goal—were not employed, since fully satisfactory examples of these types could not be generated (see the introduction to Experiment 3 below for a more complete discussion of this problem). Since the two missing combinations included one of each of the deep-structure syntactic concepts, one of each of the semantic concepts, and one of each of the surface-structure syntactic concepts, their exclusion should not bias the learning of any of these concepts. For each of the concepts learned by the subjects, three of the sentence types were instances of the given concept and three were not. For the semantic concept, the three positive types were those with experiencer (Types 1, 2, 3, Table 1) and the three negative types were those with goal (4, 5, 6); for the deep-structure syntactic concept, the three positive types were those with deep-structure subject (1, 2, 4) and the three negative types were those with deep-structure object of the preposition (3, 5, 6); for the surface-structure syntactic concept, the three positive types were those with surface-structure subject (1, 4, 5) and the three negative types were those with surface-structure object of the preposition (2, 3, 6); for the arbitrary concept, the three positive types had no regular relationship to each other (2, 4, 6) and the three negative types also were not related in any regular way (1, 3, 5).

Method

Subjects. Forty young men and women, who were recruited by posters on the Yale University campus, participated as subjects and were paid $1 for their participation, which lasted approximately 20 min. No subject had any formal training in linguistics. There were four conditions—arbitrary, deep-structure syntactic, semantic, and surface—with 10 subjects in each condition. The assignment of subjects to conditions was determined by time of arrival for testing according to a fixed rotation of conditions.

Materials. Sixty sentences, 10 of each of the six sentence types, were employed as stimuli. These sentences are shown in the Appendix. Note that for all the sentences where “John” was the surface subject, “John” was the first word in the sentence, and for all sentences where “John” was the surface object of the preposition, “John” was the last word in the sentence. Hence surface location of the word “John” was perfectly confounded with its surface-structure category but unconfounded with its deep-structure category and semantic role. Each of the 60 sentences was typed in the center of four 4 x 6 in. cards. Four decks of cards were constructed, one for each of the four conditions. Each deck included all 60 sentences; only the order of the sentences varied across decks. In each deck, the order of the sentences was pseudorandom with the constraint that each 12-sentence block included 2 sentences of each type. The sentences within a given one of the five blocks were the same in the four decks, but the order of sentences within a block differed across decks. The order of sentences in a given block in the semantic condition was the same as that in the deep-structure syntactic condition, except for the placement of four of the sentences, including two of each of two types: sentences that were positive instances of the semantic concept but negative instances of the deep-structure syntactic concept (Type 3), and sentences that were negative instances of the semantic concept but positive instances of the deep-structure syntactic concept (Type 4). The two sentences of the first type in the deep-structure syntactic deck were replaced by the two sentences of the second type, and vice versa, to form the semantic deck. However, the two sentences of a given type maintained their position relative to each other. Similarly, the order of sentences in a given block in the surface condition was the same as that in the deep-structure syntactic condition except for the placement of four of the sentences, including two of each of two types: sentences that were positive instances of the surface concept but negative instances of the deep-structure syntactic concept (Type 5), and sentences that were negative instances of the surface concept but positive instances

of the deep-structure syntactic concept (Type 2). The two
sentences of the first type in the deep-structure syntactic deck
were replaced by the two sentences of the second type, and
vice versa, to form the surface deck. The deck for the arbitrary
condition was analogously related to that of the deep-structure
syntactic condition. These relationships among the four decks
insured that the sequences of correct responses (positive and
negative instances of the given concept) were the same in all
four conditions.

Procedure. Each subject was tested individually on one of the
four concepts. The experimenter, who sat across a table from the
subject, showed the subject all the cards from the appropriate
deck, one at a time in the prescribed order. The subject was
allowed to view only the sentence currently under test at any
given instant. The subject was to respond orally "yes" or "no"
to each sentence, depending on whether he thought it was a
positive or negative instance of the concept. After the subject
responded, the experimenter supplied immediate oral feedback
by telling him whether he was correct or what the correct
answer was. The experimenter recorded the subject's responses
on an answer sheet, with an indication whether a given response
was an error. Sentence presentation was experimenter paced,
dependent on the subject's speed of responding. The following
instructions were read to the subject at the start of the experiment:

"You will be presented with a series of cards on each of
which is printed a simple sentence with the word John in it. The
word John has some kind of relation to the other words in the
sentence. Your task is to determine what the relationship is.

"When you see each card you are to judge whether the
sentence on it illustrates the test relation between John and the
other words in the sentence. Say 'yes' if you think that it does
or 'no' if you think that it does not. The experimenter will tell
you if your answer is right or wrong. You may not look back at
cards that you have already seen."

Results and Discussion

The results are summarized in Table 2 in terms of
mean percentages of errors per 12-sentence block as a
function of block position and condition. As expected,
subjects performed best in the surface condition, where
the concept to be learned was assumed to be trivial,
and worst in the arbitrary condition, where the concept to
be learned was not meaningful (except as a disjunction
of sentence types). In addition, performance was better
in the semantic condition than in the deep-structure
syntactic condition, but this difference was not
statistically significant. Two analyses of variance were
performed on these data, one with subjects (F1) and one
with sentences (F2) as the random effect. The statistic
min F* (Clark, 1973) was computed on the basis of
these analyses. These analyses yielded a significant main
effect of condition [min F*(3,46) = 9.8, p < .001;

F1(3,36) = 11.1, MSe = 5,190, p < .001; F2(3,90) =
82.4, MSe = 140, p < .001]. Newman-Keuls tests, based
on the analysis with subjects as the random effect,
revealed significant differences between the deep-
syntax syntactic condition and the surface condition
and between the arbitrary condition and the semantic
and surface conditions, all at the .01 level, as well as a
significant difference between the semantic and surface
conditions at the .05 level. No other differences among
conditions were statistically significant. In particular,
these analyses did not allow us to distinguish between
the critical semantic and deep-structure syntactic
conditions or between the deep-structure syntactic and
arbitrary conditions.

Learning was evident across the five 12-sentence
blocks; the main effect of blocks was significant [min F*(4,84) = 6.7, p < .001; F1(4,144) = 15.5, MSe = 818,
p < .001; F2(4,30) = 11.9, MSe = 212, p < .001].
Furthermore, there was more learning evident across the
five blocks in the semantic condition than in the deep-
syntax syntactic condition. Although the overall
analyses of variance did not reveal a significant
interaction of Condition by Blocks [min F*(12,128) < 1;
F1(12,144) = 1.6, MSe = 818, p = .105; F2(12,90) = 1.8,
MSe = 140, p = .054], planned analyses of variance with
only the critical semantic and deep-structure syntactic
conditions did reveal a significant interaction of
Condition by Blocks in both the test with subjects as the random
effect [F1(4,72) = 3.9, MSe = 715, p = .006] and the
test with sentences as the random effect [F2(4,30) = 2.9,
MSe = 192, p = .037], but not in the more conservative
test combining them [min F*(4,74) = 1.7, p = .163].
In addition, the planned analysis for the two critical
conditions yielded a significant main effect of condition
with sentences as the random effect [F2(1,30) = 8.0,
MSe = 192, p = .008].

The analyses of variance further revealed a significant
effect of sentence type [min F*(5,131) = 4.6, p < .001;
F1(5,180) = 7.9, MSe = 1,500, p < .001; F2(5,30) = 11.1,
MSe = 212, p < .001] and a significant interaction of
Condition by Sentence Type [min F*(15,270) = 2.6,
p = .001; F1(15,180) = 3.8, MSe = 1,500, p < .001; F2(15,90) = 8.1, MSe = 140, p < .001]. Table 3 presents
the mean percentages of errors as a function of condition
and sentence type. Clearly, certain sentence types
caused more trouble for learning some concepts than
others, but the nature of the interaction of condition
and sentence type did not appear to be completely
comprehensible and, as will be shown below, was not
entirely consistent across experiments.

These results suggest that semantic case relations
are indeed learned more rapidly than deep-structure
syntactic relations. Since the largest difference between
the semantic and deep-structure syntactic conditions was
at the last block of training, where learning was greatest,
a more sensitive test comparing these two conditions
seems to be one where all testing is conducted after
training has been completed. For that reason a new,
recognition memory paradigm was devised for Experi-
ment 2 to compare the learning of the semantic and
deep-structure syntactic relations with all testing con-
ducted after the completion of training. This paradigm,
like the concept-formation task, was designed to test
the psychological accessibility of various linguistic
concepts. Whereas the concept-formation task allowed
us to determine whether subjects could learn the given
concepts, the recognition memory task allows us to
determine whether the given concepts are discovered by
subjects in their attempts to learn a list of sentences for
a subsequent memory test.

EXPERIMENT 2

The same relations were tested in this experiment as
in Experiment 1. Furthermore, the same sentences
were employed in the two experiments, with the following
important exception: There were two versions of each of
the 60 sentences, with one version containing the word
"John," as earlier, and one version containing the word
"Sam" instead of "John." Every subject was shown each of
the 60 sentences, half of which were in the version
with "John" and half in the version with "Sam." As in
Experiment 1, there were four groups of subjects, the
groups in this case differing in the rule used to assign
"John" or "Sam" to each sentence. The assignment was
made on the basis of the deep-structure syntactic category
of the word "John" or "Sam," the semantic role, the
surface-structure syntactic category, or the arbitrarily
defined rule employed in Experiment 1. The subjects'task in this experiment was first to study the given
sentences and later, on a subsequent recognition memory
test, to decide whether a given sentence that had been
studied earlier included "John" or "Sam." In contrast to
Experiment 1, subjects were not specifically told about
the existence of a consistent relation between "John"
(or "Sam") and the rest of the words in each sentence.
Therefore, this experiment allowed us to determine how
readily the given relations were discovered by subjects
in the course of memorizing a list of sentences, rather
than whether the subjects could learn the given relations
when required to do so.

Method

Subjects. Forty young men and women, who were recruited
by posters on the Yale University campus, participated as
subjects and were paid $1 for their participation, which lasted
approximately 20 min. There were four conditions—arbitrary,
deep-structure syntactic, semantic, and surface—with 10 subjects
in each condition. For each condition, there were two subgroups
of subjects (A and B) with five subjects in each subgroup. The
assignment of subjects to conditions and subgroups was
determined by time of arrival for testing according to a fixed
rotation of conditions and subgroups.

Materials. Eight decks of cards, each card containing one
sentence, were constructed for training, two decks for each of
the four groups of subjects. For a given group, the sentences in
each deck were identical to those employed in Experiment 1,
except that in one deck (Deck A) all the sentences that were
positive instances of the concept tested in Experiment 1 included
the word "John" and all the sentences that were
negative instances of the concept included the word "Sam," and
in the other deck (Deck B) the opposite assignment of "John"
and "Sam" was employed. In each condition, one subgroup of
subjects (A) was given Deck A and the other subgroup (B) was
given Deck B. This method of counterbalancing assured that
across subjects the words "John" and "Sam" would not be
confounded with the positive and negative instances of the
concept. The order of the sentences in a given deck varied across
subjects and was determined by the experimenter's thoroughly
shuffling the deck of cards before handing it to the given subject.

Four typewritten lists of sentences were constructed for
the recognition memory test, one list for each of the four
conditions. The list for a given condition included the same
sentences as in Experiment 1 in the same order. The only
differences between the form of the sentences as they appeared
on the cards in Experiment 1 and as they appeared on the test
lists in Experiment 2 were that the sentences were numbered
(from 1 to 60) in Experiment 2 but not in Experiment 1, and
the word "John" in each sentence in Experiment 1 was replaced
by the pair of words "John/Sam" in Experiment 2. As a result of
these constraints, the order of correct answers ("John" or
"Sam") was the same for subjects in all four Subgroups A and
was the same for subjects in all four Subgroups B, but the
correct answers for subjects in Subgroups A were directly
opposite to those for subjects in Subgroups B.

Procedure. Each subject was tested individually with one of
the eight study decks of cards. The first eight subjects ran,
one in each subgroup, were given 8 min to study the list of
sentences (timed by the experimenter with a stopwatch). The
remaining 32 subjects were given 5 min to study the deck of
sentences, since the performance of the first subjects seemed to
approach the ceiling. Subjects were in no way restricted in their
method of studying the sentences. They were allowed to sort
the sentences into piles, and they were allowed to look at a
given sentence any number of times. The subjects were not
couraged to use any particular strategy in studying the
sentences. They were, however, given written instructions describing
exactly what their task would be during the recognition memory
test: "You will be presented with a stack of cards. On each card
is a sentence which involves either John or Sam. You are to
study these sentences for five [eight] minutes. At the end of
that time you will be given two sheets of paper which include
each of the sentences on the cards with the words John and
Sam replaced by John/Sam. Your task will be to recall for each
sentence whether John or Sam was involved in that sentence
as it appeared on the card. You are to indicate your response by
circling one of the two words John or Sam in the given
sentence on the sheet of paper." After studying the sentences on
the cards, subjects were reminded of their task on the recogni-
tion memory test. Subjects were then given the appropriate test
list of sentences and responded by circling the word "John"
or "Sam" in each sentence, depending on which word they
thought occurred in the sentence when it appeared on the card.
Subjects were required to respond to every test sentence; they
were not allowed to leave blanks. Subjects were given as much
time as they needed to complete the recognition memory test.

Results and Discussion

The results are summarized in Table 4 in terms of mean percentages of errors on the recognition test as a function of condition and sentence type. The data were averaged over subgroups (A and B), since that factor was not found to be significant. The difference between the deep-structure syntactic and semantic conditions in this experiment was striking. Performance on the deep-structure syntactic relations was considerably worse than on the semantic and surface relations and, in fact, somewhat worse than on the arbitrary relations. Two analyses of variance were performed on these data, one with subjects (F₁) and one with sentences (F₂) as the random effect. According to these analyses, there was a significant effect of condition [min F(3,46) = 5.5, p = .003; F₁(3,36) = 6.2, MSe = 598, p = .002; F₂(3,162) = 48.5, MSe = 77, p < .001], an effect of sentence type that approached significance [min F(5,205) = 2.1, p = .069; F₁(5,180) = 3.4, MSe = 174, p = .006; F₂(5,54) = 5.3, MSe = 112, p < .001], and a significant interaction of these two factors [min F(15,307) = 1.8, p = .029; F₁(15,180) = 2.7, MSe = 174, p = .001; F₂(15,162) = 6.0, MSe = 77, p < .001]. As in Experiment 1, certain sentence types caused more trouble for some conditions than for others. However, the nature of the interaction of condition and sentence type was somewhat different from that found in Experiment 1.

Separate planned analyses of variance were conducted with the data from just the two critical conditions (deep-structure syntactic and semantic). These analyses also revealed a significant effect of condition [min F(1,21) = 6.8, p = .016; F₁(1,18) = 7.4, MSe = 724, p = .014; F₂(1,54) = 87.8, MSe = 61, p < .001], but the effect of sentence type [min F(5,144) = 1.2, p = .337; F₁(5,90) = 1.8, MSe = 158, p = .129; F₂(5,54) = 3.3, MSe = 84, p = .011] and the interaction of condition and sentence type [min F(5,138) = 1.8, p = .113; F₁(5,90) = 2.5, MSe = 158, p = .035; F₂(5,54) = 6.5, MSe = 61, p < .001] were not significant. Furthermore, Newman-Keuls tests, based on the overall analysis conducted with subjects as the random effect, revealed significant differences (p < .05) between the deep-structure syntactic and semantic conditions, between the arbitrary and semantic conditions, and between the arbitrary and surface conditions, a significant difference (p < .01) between the deep-structure syntactic and surface conditions, and nonsignificant differences between the semantic and surface conditions and between the deep-structure syntactic and arbitrary conditions. It is clear from these data that subjects easily discovered the semantic case relations discriminating the "Sam" and "John" sentences when studying the sentences for a subsequent recognition memory test, and the subjects were not able to discover the deep-structure syntactic relations so easily. The latter concepts were discovered no more easily than purely arbitrarily defined relations.

EXPERIMENT 3

Only six sentence types were employed in Experiments 1 and 2, although there are eight possible combinations of the three kinds of relations. The two missing sentence types (7 and 8) had been excluded because it was difficult to find satisfactory examples of them. However, examples of these sentence types do exist, and one of each of these two types is shown in Table 1. The problem with sentences of these types is that the case role of "John" seems to be ambiguous. Specifically, in Type 7 sentences, "John" seems to be in both the roles of experiencer and goal, although the experiencer role does seem more salient. In some Type 8 sentences, it is not entirely clear whether "John" is in the role of goal or agent, a problem that exists for several sentences of other types as well. Despite these difficulties, all eight sentence types were employed in Experiment 3, which was otherwise a replication of Experiment 2. (Type 7 was selected to be a positive instance of the arbitrary concept, and Type 8 was selected to be a negative instance of the arbitrary concept.) This experiment enabled us to test our contention that the previous results were not due to any bias created by employing only six sentence types.

Method

Subjects. Forty male and female undergraduate students of Yale University who were taking a course in introductory psychology participated as subjects, receiving course credit. As in Experiment 2, there were eight subgrouops of subjects with five subjects in each subgroup. The assignment of subjects to subgroups was determined by time of arrival for testing according to a fixed rotation of subgroups.

Materials. Eight decks of cards were constructed for training, one deck for each of the eight subgroups of subjects. The decks were constructed in a manner strictly analogous to that employed for Experiment 2, except that there were 64, rather than 60, sentences in each deck, including 8, rather than 10, of each sentence type. The sentences employed are shown in the Appendix. The two sentences of each of the original six types included in Experiment 2 but not in Experiment 3 have an asterisk beside them in the Appendix.

Four typewritten lists of sentences were constructed for the recognition memory test in an analogous manner to the lists constructed for Experiment 2. On each list the order of the sentences was pseudorandom with the constraint that each 16-sentence block included 2 sentences of each type. The sentences within a given one of the four blocks were the same on
the four lists, but the order of the sentences within a block differed across lists. In particular, the order of the sentences in a given block in the semantic condition was the same as that in the deep-structure syntactic condition, except for the placement of eight of the sentences, including two of each of four types: sentences that were positive instances of the semantic concept but negative instances of the deep-structure syntactic concept (Types 3 and 7), and sentences that were negative instances of the semantic concept but positive instances of the deep-structure syntactic concept (Types 4 and 8). The two sentences of Type 3 in the deep-structure syntactic deck were replaced by the two sentences of Type 4, and the two sentences of Type 7 in the deep-structure syntactic deck were replaced by the two sentences of Type 8, and vice versa, to form the semantic deck. However, the two sentences of a given type maintained their position relative to each other. The lists for the surface and arbitrary conditions were analogously related to the list for the deep-structure syntactic condition. As in the earlier experiments, the relationships among the four lists insured that the sequence of correct answers ("John" or "Sam") was the same for subjects in all four Subgroups A and was the same for subjects in all four Subgroups B.

Procedure. The procedure was the same as in Experiment 2, except that all subjects were given 5 min to study the deck of sentences.

Results and Discussion

The results are summarized in Table 5 in terms of mean percentages of errors on the recognition test as a function of condition and sentence type. Despite the difference in the sentence types included, the pattern of results was strikingly similar to that found in Experiment 2. Two analyses of variance were performed on these data, one with subjects (F1) and one with sentences (F2) as the random effect. These analyses yielded a significant main effect of condition [min F(3,46) = 10.1, p < .001; F1(3,36) = 11.4, MSe = 1,024, p < .001; F2(3,168) = 84.6, MSe = 111, p < .001], but neither the main effect of sentence type [min F(7,149) = 1.1, p = .373; F1(7,252) = 2.6, MSe = 179, p = .013; F2(7,56) = 1.9, MSe = 198, p = .090] nor the interaction of condition and sentence type [min F(21,418) < 1; F1(21,252) = 1.2, MSe = 179, p = .238; F2(21,168) = 1.6, MSe = 111, p = .063] was significant.

Separate analyses of variance were conducted with the data from just the semantic and deep-structure syntactic conditions. These analyses also yielded a significant effect of condition [min F(1,121) = 7.1, p = .015; F1(1,18) = 7.6, MSe = 1,337, p = .013; F2(1,56) = 98.7, MSe = 82, p < .001]. In addition, Newman-Keuls tests, based on the overall analysis conducted with subjects as the random effect, revealed significant differences (p < .01) between the deep-structure syntactic and semantic conditions, between the arbitrary and semantic conditions, between the arbitrary and surface conditions, and between the deep-structure syntactic and surface conditions, but the differences between the deep-structure syntactic and arbitrary conditions and between the semantic and surface conditions were not significant by these tests. The conclusions reached on the basis of Experiment 2 are clearly supported by this pattern of results.

SUMMARY AND CONCLUSIONS

These experiments indicate that the deep-structure syntactic relations studied were both learned more slowly and discovered less readily than the semantic case concepts studied. These results suggest that the deep-structure syntactic relations included in the standard theory are less accessible than semantic relations and, in fact, are no more accessible than arbitrarily defined relations. An implication of these findings is that the cued-recall studies purporting to demonstrate the importance to sentence memory of the relation deep-structure subject (Blumenthal, 1967; Blumenthal & Boakes, 1967) were misleading because of their confounding deep-structure syntactic and semantic relations. The present study suggests that deep-structure syntactic relations, when unconfounded from semantic relations, do not play a major role in sentence memory.

More generally, these results favor case grammar, rather than the standard theory, in a model of linguistic behavior. It should be noted, however, that although these results are clearly difficult for the standard theory, they do not discriminate among different semantically based grammars.

Our rejection of the standard theory in a model of linguistic behavior may not seem very consequential for two reasons: First, there has been a proliferation of proposed revisions of the standard theory. However, some influential theorists have recently argued (see Bever, Katz, & Langendoen, 1976) that the dismissal of the standard theory may have been too rash. It is also relevant to note (see Footnote 1) that Fillmore, who initially rejected purely syntactic deep-structure relations, now includes them, along with case relations,

| Table 5 | Mean Percentage of Errors in Experiment 3 as a Function of Condition and Sentence Type |
|-------------------------------|-------------------------------|-------------------------------|-------------------------------|-------------------------------|-------------------------------|-------------------------------|-------------------------------|-------------------------------|
| Condition                     | 1    | 2    | 3    | 4    | 5    | 6    | 7    | 8    | Mean            |
| Surface                       | 3.75 | 5.00 | 1.25 | 2.50 | 1.25 | 3.75 | 2.50 | 6.25 | 3.28            |
| Semantic                      | 5.00 | 7.50 | 7.50 | 7.50 | 6.25 | 10.00| 6.25 | 11.25| 7.66            |
| Semantic Inst.                | 21.25| 26.25| 20.00| 30.00| 23.75| 22.50| 16.25| 28.75| 23.59           |
| Deep-Structure Syntactic      | 13.75| 31.25| 37.50| 30.00| 31.25| 37.50| 15.00| 30.00| 28.28           |
in his case grammar (Fillmore, 1977). Second, the results of a number of psychological experiments have failed to provide support for the standard theory as a basis for linguistic behavior. However, the experimental evidence against the standard theory has been evidence against the grammatical operations, not against the structural descriptions of the theory (Fodor, Bever, & Garrett, 1974). The present evidence against the standard theory pertains instead to the structural descriptions. Hence, our demonstration of the inaccessibility of deep-structure syntax is not without considerable consequence.

This study also has an important methodological implication. In studying the relative accessibility of various linguistic concepts, the new recognition memory paradigm developed here seems to be more sensitive than the traditional concept-formation task. Two factors may have been responsible for the increase in sensitivity: (1) All testing occurred after training was completed in the memory paradigm. (2) The memory paradigm tested whether a given concept would be discovered by the subject rather than whether the concept could be learned by the subject.

*Sentences used in Experiments 1 and 2 but not in Experiment 3.

REFERENCES

NOTES

1. In a more recent paper, Fillmore (1977) has recognized the need for purely syntactic deep-structure relations as well as case relations.

2. Although Fillmore (1968) originally represented deep structures in terms of tree structures, as in Figure 2, more recently, Fillmore (1971) has announced a preference for a different type of notation.

3. We employed the definitions for these cases given by Fillmore (1971) and restricted ourselves to the benefactive meaning of the goal case: "Where there is a genuine psychological event or mental state verb, we have the Experiencer; ... where there is a transfer or movement of something to a person, the receiver as destination is taken as the Goal" (Fillmore, 1971, p. 42).

(Received for publication April 24, 1978; revision accepted July 10, 1978.)
